Abstract The objective was to construct a laparoscopic transabdominal isthmic cerclage in a patient with cervical agenesis at Kadir Has University, Metropolitan Florence Nightingale Hospital. A 39-year-old woman diagnosed with primary infertility due to cervical agenesis was admitted to our hospital because of recurrent assisted reproductive technique (ART) failures. She underwent three operations for acute abdominal pain due to endometriosis and pyometra. There was a tiny fistula-like opening at the level of the isthmus, through which menstrual blood passed. Three intracytoplasmic sperm injection (ICSI) attempts with transmyometrial transfer had failed at three different IVF centres. We performed a laparoscopic transabdominal isthmic cerclage to prevent a miscarriage due to a clinical condition similar to cervical insufficiency and then an ICSI procedure was performed. We delivered a healthy baby weighing 3,200 g by Caesarean section. We left the cerclage in place for subsequent pregnancies. To the best of our knowledge, this is the first report of laparoscopic isthmic cerclage for the prevention of a clinical condition similar to cervical insufficiency in cervical agenesis that has resulted in a term pregnancy after ICSI.

Keywords Laparoscopic cerclage · Abdominal cerclage · Cervical agenesis · Cervical insufficiency · ICSI

Introduction

Cervical incompetence has been acknowledged as a significant entity predisposing patients to second trimester miscarriage. Various surgical techniques have been used to prolong pregnancy and improve prenatal outcome. These

include transvaginal and transabdominal cervical cerclage applied preconceptionally or during pregnancy.

Here we report a case of 39-year-old-woman with cervical agenesis and infertility, in which laparoscopic isthmic placement of cerclage was performed before embryo transfer, resulting in a successful pregnancy.

Case report

A 39-year-old woman was admitted to our hospital with the diagnosis of primary infertility. When she was 15 years old, she consulted a gynaecologist because of acute abdominal pain. In her gynaecological examination, the cervix uteri could not be visualised and in the ultrasonographic examination bilateral endometriomas and haematometra were seen. A laparotomic cystectomy was performed and an incision was made at the level of the isthmus to let menstrual bleeding occur. During her reproductive period, she suffered from acute abdominal pain and she underwent three operations for pyometra and haematometra, and the incision was repeated for patency of the blocked passage. She had been married for 20 years and was unable to achieve a spontaneous pregnancy. In 1999, the couple attended an infertility clinic and her husband's spermogram revealed severe oligospermia. In her gynaecologic examination, the cervix could not be visualised and it was noted that the vaginal cuff had a post-hysterectomy appearance. A diagnostic laparoscopy was carried out and severe adhesions were reported because of endometriosis and laparotomies. Three cycles of intracytoplasmic sperm injection (ICSI) and transmyometrial embryo transfer were performed. Although three or four embryos of good quality were transferred at every attempt, pregnancy was not achieved. In a university hospital, it was concluded that the couple could never have a baby because of cervical agenesis.

The patient was evaluated at our centre in January 2004. We performed a gynaecologic examination, but were unable to see the cervix. We invited the patient to be re-examined at the beginning of her menstrual period in order

to see where the blood was going. She had severe dysmenorrhoea because of the narrow opening at the right side of the vaginal end. The fistula-like opening probably occurred because of the repeated incisions at the level of the isthmus. We decided to place an isthmic cerclage before IVF for a successful outcome.

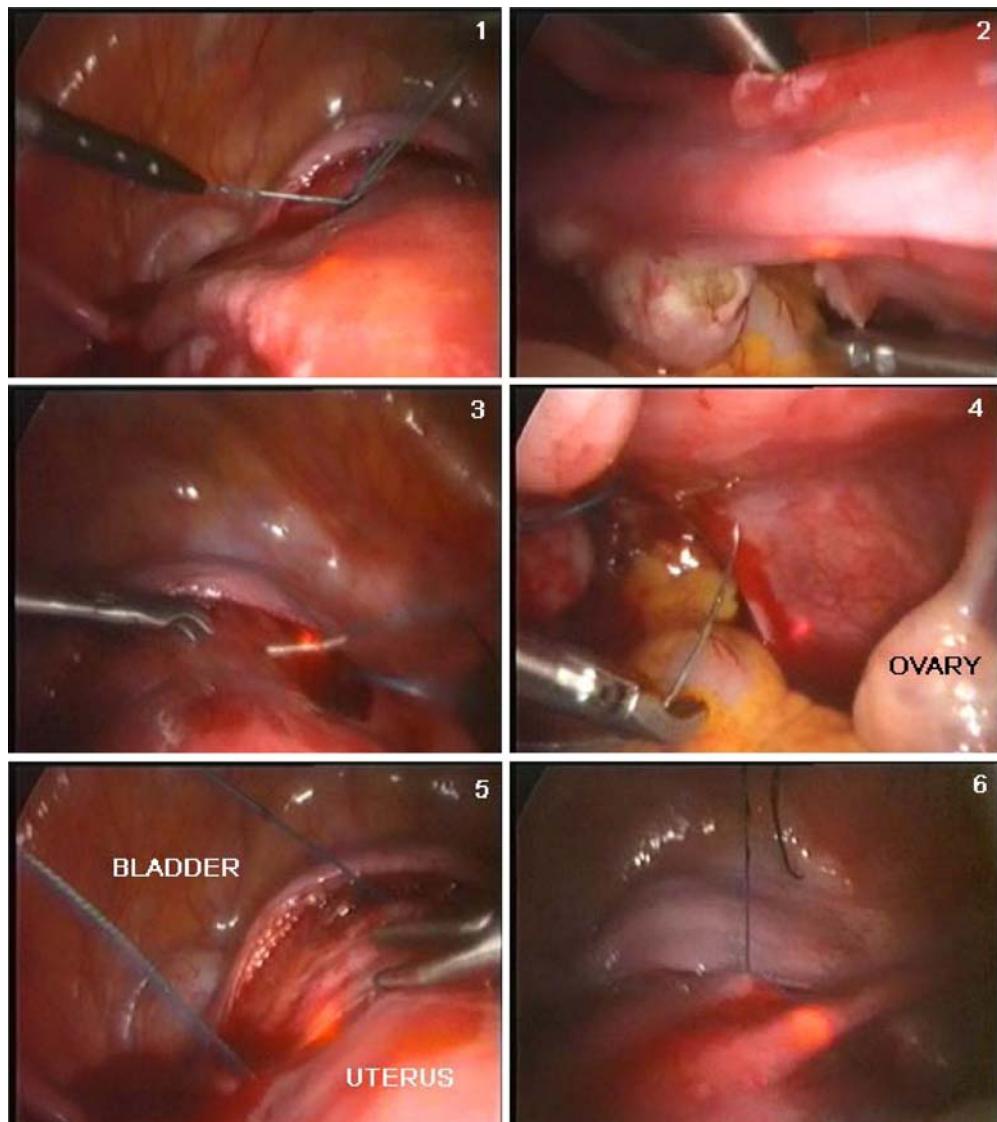

Under general anaesthesia, the patient was placed in the dorsal lithotomy position, and a Foley catheter was inserted. The anterior vaginal wall neighbouring this narrow passage was grasped with a tenaculum and the passage was dilated with an 8-mm Hegar bougie under ultrasound and laparoscopic guidance. The Hegar bougie was placed and secured with a tenaculum and was not removed during the operation (Fig. 1). Then a laparoscopy was performed with three puncture sites, using the umbilical one for the laparoscope. The second and third ones were made in the suprapubic area. At the beginning of the surgical procedure, the adhesions were lysed using a CO₂ laser and then the uterovesical peritoneum was incised transversely again with the laser, where the reflection of the

bladder was seen. A non-absorbable prolene suture (No 2, Ethicon; Johnson & Johnson, Istanbul, Turkey) was used. When the vesico-uterine space was opened, the bladder was pushed down. The ligature was passed through from the anterior and towards the posterior parts of the isthmus, and it was knotted at the level of the sacro-uterine ligaments.

After confirming that the ligature was in an appropriate place at the isthmus, the ends of the ligature were knotted. The peritoneum was sutured over the knot and the laparoscopy was finalised following haemostasis. The suture was left in place for subsequent pregnancies.

Two months later, we started controlled ovarian stimulation with recombinant follicle stimulating hormone (FSH; Puregon; Organon, Altunizade, Turkey) at 200 IU/day. We obtained 20 oocytes and 14 of them were metaphase II. We transferred two embryos on the 3rd day; both of them were reported to be Grade 1. The beta human chorionic gonadotrophin (HCG) level on the 11th day of embryo transfer was 223 mIU/ml. During pregnancy, in the 32nd

gestational week, there was a risk of pre-term labour, after which only bed rest was recommended. The antenatal follow-up showed no abnormality and she delivered a healthy male baby weighing 3,200 g in the 38th gestational week by Caesarean section.

Discussion

Cervical incompetence is a premature dilatation of the cervix leading to recurrent mid-trimester pregnancy loss or early premature labour. It is thought that the condition is caused by a defect in the strength of the cervical tissue either congenitally or acquired, resulting in the inability to maintain a pregnancy [1]. The treatment consists of placing a purse string suture around the cervix. The conventional method is placing the sutures vaginally, but it might not be possible in extremely short, deformed and scarred cervices or in the absence of a cervix. Abdominal cerclage has been advocated by several authors to overcome this problem.

The indications for abdominal cerclage are as follows: congenitally short cervix, extensively amputated cervix, marked scarring of the cervix, deep and jagged multiple cervical defects, and previously failed vaginal cerclage [2]. There are no studies in the literature showing that cervical agenesis always results in cervical insufficiency; however, an endoscopic cerclage operation was performed in our patient, since she had undergone several operations for haematometra and there was irregular fistula formation at the level of the isthmus, which could be a reason for a second trimester miscarriage. A review of the literature is shown in Table 1.

In 1965, Benson and Durfee first described the transabdominal cervico-isthmic cerclage by laparotomy in a group of women with cervical incompetence in whom a

conventional transvaginal procedure was impossible [3]. Since then, these operations have been performed during pregnancy or before conception to prevent cervical insufficiency [4, 5]. A less invasive approach is laparoscopic abdominal cerclage, which has the advantages of a laparoscopic procedure including no hospitalisation, less postoperative pain, and faster recovery [2].

In 1998, Scibetta and colleagues described the first case of the successful use of an interval laparoscopic technique for transabdominal cerclage placement, so as to avoid the need to resort to a laparotomy during the pregnant or non-pregnant state [6], but this case and all subsequent cases had normal cervical anatomy.

Gallot and colleagues reported the use of laparoscopic transabdominal cerclage in three women with a history of recurrent miscarriages and failed cerclage. All procedures were successful and two of them became pregnant within 4 months, delivering by Caesarean section at 38 weeks' gestation [7].

Conclusion

In the case presented, the failure of previous assisted reproductive technique (ART) cycles can be attributed to transmyometrial transfer, which caused bleeding. We created an artificial cervical canal through which we carried out the transfer of the embryos. There is only one study in the literature reporting transvaginal cerclage being performed in cases of severe cervical hypoplasia under ultrasound guidance [8]. To the best of our knowledge, this is the first report of transabdominal laparoscopic isthmic cerclage performed for cervical agenesis that has resulted in a successful pregnancy and a healthy baby following ICSI.

Table 1 Reproductive outcomes after laparoscopic abdominal cerclage

Authors	Number of Cases	Age (years)	Cerclage in pregnancy	Indication	Pregnancy outcome
Al-Fadhli and Tulandi [2]	2	36, 38	No	Failed cerclages	One term pregnancy, one not pregnant
Darwish and Hassan [9]	1	31	Yes	Eight failed cervical cerclages	Live birth, 37 weeks
Gallot et al [7]	3	26, 35, 29	No	Failed cervical cerclages	Two live births at 38 weeks; one not pregnant
Henricus et al. [10]	1	34	No	Short cervix after wide excision followed by immature delivery	Live baby with intrauterine growth restriction, 37 weeks
Ind and Mason [11]	1	33	No	Two failed cervical cerclages	Not reported
Lessor et al [12]	1	40	Yes	Failed cerclage, diethylstilbestrol exposed, and mid-trimester miscarriage	Live birth, 35 weeks
Mingione et al. [4]	11	22–39	No	Absent or short cervix or failed cervical cerclages	Ten term live births, one elective delivery at 34.5 weeks
Scibetta et al. [6]	1	37	Yes	Absence of exocervix following cone biopsy	Live birth, 38.5 weeks
Present case	1	39	No	Cervical agenesis	Live birth, 38.5 weeks
