MASTER'S THESIS

Submitted to the Graduate School of Science and Engineering of  
Kadir Has University in partial fulfillment of the requirements for the degree of  
Master of Science in Program of Computational Biology and Bioinformatics

ISTANBUL, JUNE, 2021

## DECLARATION OF RESEARCH ETHICS / METHODS OF DISSEMINATION

I, MEHMET EYMEN SÜMER, hereby declare that.

- this master's thesis is my own original work and that due references have been appropriately provided on all supporting literature and resources.
- this master's thesis contains no material that has been submitted or accepted for a degree or diploma in any other educational institution.
- I have followed "Kadir Has University Academic Ethics Principles" prepared in accordance with "The Council of Higher Education's Ethical Conduct Principles".

In addition, I understand that any false claim in respect of this work will result in disciplinary action in accordance with university regulations.

MEHMET EYMEN SÜMER

TARİH VE İMZA

## ACCEPTANCE AND APPROVAL

This work entitled **ENHANCED OPTICAL, STRUCTURAL AND ANTIBACTERIAL PROPERTIES OF ZnO DOPED TiO<sub>2</sub> COMPOSITES** prepared by **Mehmet Eymen Sümer** has been judged to be successful at the defense exam held on 14.07.2021 and accepted by our jury as **MASTER'S THESIS**.

APPROVED BY:

## **ENHANCED OPTICAL, STRUCTURAL AND ANTIBACTERIAL PROPERTIES OF ZnO DOPED TiO<sub>2</sub> COMPOSITES**

### **ABSTRACT**

In daily life, bacterial infections are common issues for human health. Thus, researchers are searching for valuable materials to prevent antibacterial infections and environmental pollutants. Thin film is a well-known application for photocatalytic and biological activity. Hence, thin-film formation is an excellent way to overcome these problems due to its nanosize thickness and enhanced monolayer or a multilayered structure. The most common material for the production of a thin film is titanium oxide (TiO<sub>2</sub>). It has various traits to enhance the activity of thin films, such as structural and optical properties. However, single usage of pure TiO<sub>2</sub> has some limitations over these problems. Therefore, new techniques need to be implemented to overcome these limitations, and it is called doping. Doping is a standard method for manipulating material properties to provide enhanced functionality.

Thus, ZnO was selected as a dopant due to its good bandgap energy and high electron activity. Therefore, this thesis mainly focused on the antibacterial, structural, and optical activity differences of pure TiO<sub>2</sub> and ZnO doped TiO<sub>2</sub>. Within several different thin film deposition methods, the sol-gel method was used in this research due to its easy progression at room temperature, low cost, and homogeneity traits. UV-vis spectrophotometer (Labomed Spectro 22) was used for optical analysis in the spectral range of 190–1100 nm wavelengths. Structural differences include homogeneity and particle size were determined by an X-ray diffractometer (XRD, Philips PW-1800). Antibacterial activity of pure and doped TiO<sub>2</sub> thin films was analyzed by the standard of ISO 22196 protocol against gram-positive “Staphylococcus aureus” and gram-negative “Escherichia coli”. As a result, XRD and UV-vis spectrophotometer measurements show that our dopant ZnO efficiently enhances the bandgap energy of pure TiO<sub>2</sub>, and the correlation between dispersibility and homogeneity was achieved in the concentration range of ZTA-B-R (5-10).

## **ZnO KATKILI TiO<sub>2</sub> KOMPOZİTLERİN GELİŞTİRİLMİŞ OPTİK, YAPISAL VE ANTİBAKTERİYEL ÖZELLİKLERİ**

### **ÖZET**

Günlük yaşamda bakteriyel enfeksiyonlar insan sağlığı için yaygın bir sorundur. Bu nedenle araştırmacılar, antibakteriyel enfeksiyonları ve çevresel kirleticileri önlemek için değerli materyaller arıyorlar. İnce film, fotokatalitik ve biyolojik aktivite için iyi bilinen bir uygulamadır. Bu nedenle, ince film oluşumu, nano boyutlu kalınlığı ve geliştirilmiş tek katmanlı veya çok katmanlı yapısı nedeniyle bu sorunların üstesinden gelmek için mükemmel bir yoldur. İnce film üretimi için en yaygın malzeme titanyum oksittir (TiO<sub>2</sub>). Yapısal ve optik özellikler gibi ince filmlerin etkinliğini arttırmak için çeşitli özelliklere sahiptir. Bununla birlikte, saf TiO<sub>2</sub>'nin tek kullanımı bu problemlerde bazı sınırlamalara sahiptir. Bu nedenle, bu sınırlamaların üstesinden gelmek için yeni tekniklerin uygulanması gerekir ve buna doping denir. Doping, gelişmiş işlevsellik sağlamak için malzeme özelliklerini manipüle etmek için standart bir yöntemdir.

Bu nedenle, iyi bant aralığı enerjisi ve yüksek elektron aktivitesi nedeniyle ZnO katkı maddesi olarak seçilmiştir. Böylece, bu tez temel olarak saf TiO<sub>2</sub> ve ZnO katkılı TiO<sub>2</sub>'nin antibakteriyel, yapısal ve optik aktivite farklılıklarına odaklanmıştır. Diğer farklı ince film biriktirme yöntemleri içinde, oda sıcaklığında sürecin kolay ilerlemesi, düşük maliyeti ve homojenlik özellikleri nedeniyle bu çalışmada sol-jel yöntemi kullanılmıştır. UV-vis spektrofotometre (Labomed Spectro 22), 190–1100 nm dalga boyu spektral aralığında optik analiz için kullanılmıştır. Homojenliği ve parçacık boyutunu içeren yapısal farklılıklar, X-ışını difraktometresi (XRD, Philips PW-1800) tarafından belirlenmiştir. ISO 22196 protokolü standardına göre gram pozitif “Staphylococcus aureus” ve gram negatif “Escherichia coli”ye karşı saf ve katkılı TiO<sub>2</sub> ince filmlerin antibakteriyel aktivitesi analiz edilmiştir. Sonuç olarak, XRD ve UV-vis spektrofotometre ölçümleri, katkı maddesi ZnO'nun saf TiO<sub>2</sub>'nin bant aralığı enerjisini verimli bir şekilde arttırdığını ve ZTA-B-R (5-10) konsantrasyonu aralığında dağılıbilirlik ve homojenlik arasındaki korelasyonun sağlandığını göstermiştir.

**Anahtar Sözcükler:** İnce film, TiO<sub>2</sub>, ZnO, Katkılama, Sol-jel, XRD, UV-vis spektrofotometre, Antibakteriyel.

## **ACKNOWLEDGEMENTS**

I would like to thank my advisor (Assoc. Prof. Bengü Özuğur Uysal) for her guidance and support. I would also like to thank all my faculty members of the Computational Biology and Bioinformatics Department. Last but not least, I would like to thank my family, friends, and colleagues for their support and encouragement.

## 1. INTRODUCTION

Material science and bioengineering are important majors of human life. Thus, a collaboration of these two different majors can be beneficial for biotechnological advancement. This thesis mainly focused on discovering valuable materials which can be used in biomedical applications or environmental remediation. Before starting the research, materials need to be determined and selected according to their different usage areas. In this research, primary materials need to be multifunctional. Therefore, the primary material is chosen according to its multifunctional capability in both biology and material science. Titanium oxide ( $\text{TiO}_2$ ) is one of the best favorable materials for its unique traits. Titanium oxide ( $\text{TiO}_2$ ) is also promising material due to its photocatalytic, semi-conductive, high degradation, easy to process, and low-cost traits (Luttrell et al., 2014). Titanium oxide ( $\text{TiO}_2$ ) is commonly used for thin-film and coating applications. However, sometimes using single material can produce some problems because of materials' limitations, and often, these limitations are overcome by using dopants. A cross-section of these limitations needs to be handled correctly to get the desired result (Firdaus et al., 2012).

Therefore, the addition dopants need to be selected to synergize with titanium oxide and overcome its limitations. Every dopant has different bandgap energy, recombination rate, electron mobility, surface structure, and other features. Thus, dopants generally enhance the activity of primary material due to their beneficial effects on structural, morphological, chemical, and physical traits (Khlyustova et al., 2020). Therefore, dopants' addition may manipulate the  $\text{TiO}_2$  main features such as surface area, recombination rate, bandgap energy level, optical and other traits (Khlyustova et al., 2020). For example, recent research shows that zinc oxide  $\text{ZnO}$  (wurtzite); has good electron activity at room temperature and has expansive bandgap energy compared to  $\text{TiO}_2$  phases (Firdaus, Rizam, Rusop, & Hidayah, 2012). Therefore,  $\text{ZnO}$ -doped  $\text{TiO}_2$  and three pure  $\text{TiO}_2$  phases were used for the experimental process.

In this thesis, the sol-gel method primary method for the preparation of thin films. The sol-gel method creates highly efficient and homogenous thin films with low cost and less

time consumption. One of the main advantages of using the sol-gel method is to create homogenous material at room temperature. Homogeneity and sustainability are too essential for biomedical applications, and the sol-gel method can provide these traits by controlling the reaction's stoichiometry without creating unwanted residue (Pant et al., 2019). In characterization and determination of structural, optical and antibacterial traits of  $\text{TiO}_2$  was achieved by several instruments such as UV-vis spectrophotometer, XRD and ISO 22196 protocol, respectively. UV-vis Spectrophotometer was provided absorbance values of different doped and undoped materials (Skoog, West, Holler, & Crouch, 2004). After this measurement, resonance ratio and normalize width calculation done for the homogeneity testing. Homogeneity and sustainability necessary for  $\text{TiO}_2$  studies due to its applications areas include biomedical and environmental areas. Thus homogeneity determination process is achieved by tracking the correlation between resonance ratio and normalize width. These two measurements give the homogeneity and dispersibility trait of materials (Tan & Resasco, 2005). Bandgap energy manipulation is significant for the photocatalytic and antibacterial activity of  $\text{TiO}_2$ . Energy band gap correlation between doped and undoped composites was achieved by using the Tauc plot. It demonstrates the direct and indirect conductivity levels of different composites  $\text{TiO}_2$  is an indirect semiconductor, and  $\text{ZnO}$  is a direct conductor, and the combination of these two materials tends to go either indirect or direct (Firdaus et al., 2012). Determination of these conductivity levels was found using the Tauc intensity- wavelength graphs. XRD analysis shows the average particle size of doped and pure  $\text{TiO}_2$  materials. The addition of new materials tends to create impurities, but using the sol-gel method prevents this problem and provides a good result for the brookite phase and a minor advancement for the anatase and rutile phase. However, the experimental result shows that our doping process provides a promising result for further implementation and hints at which concentration levels are critical for structural, optical, and antibacterial enhancement.

## 2. LITERATURE REVIEW

### 2.1 General Information about TiO<sub>2</sub>

Titanium dioxide (TiO<sub>2</sub>) is the second transition metal, and it is a valuable material for material science and biomedicine. William Gregor discovered TiO<sub>2</sub> in 1791, and Heinrich Klaproth isolates it. Titanium dioxide (TiO<sub>2</sub>) has a bright white color, and it has three crystalline phases: anatase, brookite, and rutile (Zhang & Banfield, 2014). Titanium dioxide (TiO<sub>2</sub>) is an excellent semiconductor in terms of bandgap energy, such as anatase 3.20 eV, rutile 3.00 eV, and brookite 3.13 eV (Linsebigler, Lu, & Yates, 1995; Thiagarajan, Sivakumar, & Rajangam, 2016; Wang, He, Lai, & Fan, 2014). The anatase and brookite phases naturally transform into the rutile phase under high temperatures, and this trait makes the rutile phase the most stable phase (Zhang & Banfield, 2014). Its morphology highly depends on its phase differences and chemical manipulation, such as dopant addition. In addition, titanium dioxide (TiO<sub>2</sub>) has multifunctional traits such as high recombination rate, biodegradability, and photocatalytic activity in higher temperatures (I M Joni, 2018). TiO<sub>2</sub> is used in various areas such as dye-sensitized solar cells, ion batteries, gas sensors, filters, light sensors, humidity sensors, hydrogen sensors, tissue engineering, biomedical and biodegradable treatments, industrial dyes, textile, and environmental remediation. (I M Joni, 2018).

### 2.2 TiO<sub>2</sub> Phases and Usage Areas

Anatase, brookite and rutile are the three main phases of TiO<sub>2</sub> (Luttrell et al., 2014). All these phases have distinct abilities and provide different advantages due to their different structural and chemical activity. For example, anatase has a tetragonal structure, and brookite has an orthorhombic structure (Zhang & Banfield, 2014). Moreover, the anatase phase is the initial phase formed in many applications, and then it transforms brookite and rutile in high temperatures, respectively.

Anatase has the largest bandgap than others phases and this trait making anatase more photocatalytic than the others (Luttrell et al., 2014). However, rutile can be more stable in higher temperatures, and it has the highest refractive index (Joni, 2018). Transformation of anatase to the rutile phase is irreversible. Brookite is rarely seen compared to anatase and rutile because its production is too hard for lab conditions.

However, brookite has the most significant cell volume, and that feature makes the brookite phase valuable for biomedical and environmental treatments (Zhang & Banfield, 2014) . Many studies show that mixed phases are more impactful than pure TiO<sub>2</sub> because of their limitations (Kumar et al., 2021). Literature reviews about TiO<sub>2</sub> phases and usage areas are a good starting point for understanding the advantages of different phases over different activities (Table 2.2.1).

**Table 2.2.1. Industrial usage of TiO<sub>2</sub> according to its phase.**

| <b>TiO<sub>2</sub> Phase</b> | <b>Industrial Usage</b>                             | <b>References</b>   |
|------------------------------|---|---|
| Rutile                       | Antibacterial agent                                 | (Zainab, Olfat, & Faisal, 2019)   |

The rutile TiO<sub>2</sub> phase is essential for various applications in biomedicine, dye-sensitized solar cells, industrial dye, supercapacitors, hydrogen sensors, textile, tissue engineering, dye-sensitized solar cells, supercapacitors, tissue engineering, hydrogen sensor, and sunscreen. Therefore, several experiments related to the rutile phases in literature were determined to benefit our research. In general, positive charges in liquid carried by metal oxide and negative charges are transported by a microorganism. This statement shows that metal oxide and microorganisms attract each other in liquid. Therefore, metal oxides are essential for treatment in antibacterial agents, and chemical attraction between these two can kill the microorganisms.

Furthermore, TiO<sub>2</sub>'s unique traits, such as its small size and high surface area, make them an excellent antibacterial agent (Zainab et al., 2019). In the dye-sensitized solar cell area, TiO<sub>2</sub> usage has been increased. Thus, regulating photoanode with doped TiO<sub>2</sub> can be so valuable due to its high surface area. As a result, doped TiO<sub>2</sub> based photoanode provides power conversion efficiency (PGE) due to increased charge transferability and bandgap energy level over other materials. This type of coordination can develop the solar cell industry without using harmful materials (Qureshi et al., 2021).

On the other hand, a combination of materials can increase the activity of the material. For example, graphene oxide (GO) is a promising remediation material because of its large surface area (2630 m<sup>2</sup>/g). According to this trait, using graphene with TiO<sub>2</sub> may increase their photocatalytic activity. Furthermore, in reduced graphene oxide (GO) - TiO<sub>2</sub> showed good degradation traits compared to the single TiO<sub>2</sub>. This information shows that doped TiO<sub>2</sub> can be more efficient than pure TiO<sub>2</sub> due to bandgap energy and recombination rate enhancement. This degradation enhancement was beneficial for industrial dye production (Ojha & Thareja, 2020).

Besides all the good traits of TiO<sub>2</sub>, it has a relatively poor conductivity rate and low capacitive capability creates some problems. However, changing TiO<sub>2</sub> morphology can eliminate these minor problems and boost its capacitive capability. Doping TiO<sub>2</sub> with Nitrogen dopants shows this enhanced capacitive activity. The addition of Nitrogen(N) can overcome the limitation of TiO<sub>2</sub> and boost their capacitive rate by increasing the charge transportation of TiO<sub>2</sub> (Su et al., 2021). The textile industry is crucial for the world economy, producing textile dyes and pigments generally done by the chemical process.

However, their absorptive and reflective ability over sunlight creates environmental problems for some microorganisms.

Moreover, the end product of these materials is primarily carcinogenic and mutagenic.  $\text{TiO}_2$  has a small spectrum range (400-700nm); hence, dopant addition is crucial for environmental treatments. For example, doping  $\text{TiO}_2$  with non-metals can increase the required wavelength range of  $\text{TiO}_2$  for photocatalytic activity on visible light by changing the bandgap energy level or recombination rate (Ambigadevi et al., 2021). Tissue engineering studies have arisen recently. Tissue engineering is vital for medical advancement because many people lose their tissues or organs due to medical or physical conditions. In this manner, some materials vital for the stability and longevity of products. In tissue engineering, biocompatibility and cytotoxicity are highly important.  $\text{TiO}_2$  is known as good antibacterial material, and these traits make  $\text{TiO}_2$  impactful on tissue engineering.

$\text{TiO}_2$  - based chitosan/sodium alginate nanocomposite was used in some experiments. Their test against human bladder tumor (UC6) and osteosarcoma (MG-62) cell lines result were promising. Their antibacterial traits were tested on *Escherichia coli*, and *staphylococcus aureus* also provides a good result. Both studies show that the chemical and physical attribution of  $\text{TiO}_2$  based nanocomposite provides good biocompatibility, which means  $\text{TiO}_2$  -based nanocomposite can be suitable for tissue engineering processes (Kolathupalayam Shanmugam et al., 2020). Breakdown of antibiotics and other drug waste is vital for environmental pollution. According to this problem, the breakdown of some commercial drugs needs to be studied. For example, the breakdown of amoxicillin is important for the drug industry.  $\text{TiO}_2$  with tungsten oxide ( $\text{WO}_3$ ) was studied and provided good results on the degradation of drug waste due to the photocatalytic activity of the  $\text{TiO}_2$  composite.

$\text{TiO}_2$  with tungsten oxide ( $\text{WO}_3$ ) inhibits the amoxicillin end product and other impurities. However,  $\text{TiO}_2$  with tungsten oxide ( $\text{WO}_3$ ) underperformed over commercial  $\text{TiO}_2$ , but it still decreases the number of byproducts from the drug. This result shows the importance of doped-  $\text{TiO}_2$  material over drug activity and wastewater degradation.

Bioproducts such as sunscreens are also an essential topic for biomedical science due to their effect on the human body.  $\text{TiO}_2$  with natural sun blocker-lignosulfonate (LS) - can enhance the photocatalytic activity of  $\text{TiO}_2$ . After the chemical alteration of two materials,

self-doping of hydroxylated TiO<sub>2</sub> and lignosulfonate (LS) oxidation increases the UV protection. This result shows that TiO<sub>2</sub> @LS composite can be used on sunscreen to prevent the harmful effect of UV light (Yu et al., 2018).

The anatase TiO<sub>2</sub> phase is essential for various applications in the antibacterial treatment, photocatalytic reactor, humidity sensor, wastewater treatment, a gas sensor for acetone detection, dye-sensitized solar cell, lithium-ion anodes, H<sub>2</sub>S gas sensor. Several experiments related to the anatase phases in literature were determined for the benefit of our research. In recent studies show that using laser irradiation can enhance the activity of TiO<sub>2</sub> and its antibacterial activity. Besides UV activation, laser irradiation can provide new paths for TiO<sub>2</sub> activity. Furthermore, the thickness of the TiO<sub>2</sub> films can be manipulated with different laser irradiation, and this morphological advancement changes TiO<sub>2</sub> activity.

However, increasing heat creates mixed phases due to TiO<sub>2</sub> morphology-shifting anatase phase to rutile phase- and tends to affect homogeneity. Moreover, irradiation triggers antibacterial growth inhibition due to the increased photocatalytic activity of TiO<sub>2</sub>. Therefore, laser irradiation can be appropriately applied for future studies to enhance the antibacterial activity of TiO<sub>2</sub> (Medvids et al., 2021). In another biomedical usage of TiO<sub>2</sub> is oral biofilm applications as a coating material. Different phases of TiO<sub>2</sub> -control, anatases, rutile, and anatase-rutile-were tested against three different species: *Streptococcus sanguinis*, *actinomyces naeslundii*, and *fusobacterium nucleatum*. As a result, a single anatase and anatase-rutile mixture can reduce bacterial activity and can be used on oral biofilms (Pantaroto et al., 2018). Thus, the plant leaf extract is used in medicine and other biomedical application. However, some studies suggest that the usage of plant extract with TiO<sub>2</sub> also enhances the photocatalytic activity of the material. For example, *Plectranthus amboinicus* leaf extract is used to synthesize TiO<sub>2</sub> nanoparticles.

The extracted TiO<sub>2</sub> nanoparticle treated with Indium tin oxide (ITO) and Rose Bengal (RB) dye to create dye-sensitized solar cells (DSSCs). Besides average DSSCs environmental pollution, TiO<sub>2</sub>-based DSSCs can be more beneficial for the environment due to the power conversion and antibacterial activity of TiO<sub>2</sub>. These TiO<sub>2</sub> based materials convert solar energy into electrical energy. Conversion of energies provides an excellent approach for wastewater treatment and reducing the waste product of non- TiO<sub>2</sub> DSSCs (Rajendhiran et al., 2021). Doping TiO<sub>2</sub> with other metals can be beneficial for

various applications. In this case, TiO<sub>2</sub> was doped with a silver (Ag) for antibacterial activity examination. Silver (Ag) is known as a good dopant material and is used in various applications. However, doping TiO<sub>2</sub> with a silver (Ag) and track their activity is crucial for clinic applications and material science. In addition, some studies show that Ag-doped TiO<sub>2</sub> can provide %100 antibacterial inhibition against Escherichia coli. Therefore, the synergetic reaction of Ag-doped TiO<sub>2</sub> is an excellent antibacterial material for biomedical applications (Li et al., 2013). Humidity sensors are crucial for human life. Producing humidity sensors relied on Cu-doped TiO<sub>2</sub> based nanocomposites can be enhanced the activity and balance of the sensor. Cu-doped nanocomposites show great promise for humidity sensors because Copper (Cu) can reduce the band gap value of TiO<sub>2</sub>, thus increase the water molecule detection. The addition of a dopant can change the electrical traits of TiO<sub>2</sub> and increase its sensitivity. Most of the time, dopants increase the bandgap energy of TiO<sub>2</sub> but in some studies, reduction of band gap also beneficial for some applications (Farzaneh et al., 2019).

The mixed nanocomposite has various beneficial traits over wastewater treatment due to photocatalytic activity. One of them is hybrid nanostructured graphene-Pt/ TiO<sub>2</sub> studies. This hybrid nanocomposite can a breakdown of methylene blue (MB) dye under sunlight. Dopants on the high surface area enhance visible light interaction and increase the separation and transportation of electron/ hole pairs. In addition, Pt/ TiO<sub>2</sub> nanostructure provides excellent stability for the breakdown and removal of methylene blue (MB).

As a result, hybrid nanocomposites can be helpful on various treatment and still needs to examine with a different dopant concentration and fixation (Ghoury et al., 2018).

In human life, diabetes is a highly abundant disease. In some studies show that TiO<sub>2</sub> can be helpful to sense the gas presence. In biomedical treatment, TiO<sub>2</sub> may be used to detection of acetone. In one study, candle soot used as a dopant and enhance the activity range of TiO<sub>2</sub> to create an acetone sensing detector. A combination of soot and TiO<sub>2</sub> can highly photoactive and detect low UV intensities. These nanocomposites can be used as a sensitive layer to sense acetone presence by tracking the UV intensities. As a result, this sensitive layer can detect the acetone presence in humans and show their diabetes (Sabri et al., 2018).

The TiO<sub>2</sub> brookite phase is rarely seen in lab conditions due to its production process more complex than other phases, and most of the time, it is used with a combination of other phases—several experiments related to the brookite phases in literature determined for the health of our research. For the brookite phase, photoluminescence enhancement, photocatalytic disinfection of bacteria, shockwave resistance and energy storage, environmental remediation, biodegradation, and wastewater treatment was determined.

In the photoluminescence study, Nickel (Ni) and carbon (C) were used as doping materials for photoluminescence enhancement. Photoluminescence (PL) of engineered TiO<sub>2</sub> is a promising technology for optoelectronic device improvement.

In general, tuned doping materials improve photocatalytic efficiency, but suitable materials need to be found with several experiments to achieve good results. Ni and carbon are the best suitable material the enhanced photoluminescence enhancement. Doping with Ni decreased the surface resonance. The formation of the brookite phase enhances the crystallization of the layer at low temperatures. Transformation of TiO<sub>2</sub> from crystalline brookite to an amorphous state using low temperatures can boost PL activity (Lamouchi et al., 2021).

It is so important to distinguish the photocatalytic activity rate of different types of crystalline phases. Mixing phases is a suitable determination method for photocatalytic activity, such as anatase-brookite, anatase-brookite-rutile, and anatase-rutile.

For example, TiO<sub>2</sub> phases have different band gaps, such as anatase 3.20 eV, rutile 3.00 eV, and brookite 3.13 eV, respectively (Linsebigler et al., 1995; Thiyagarajan et al., 2016; Wang et al., 2014).

Due to their different bandgaps, their photocatalytic activity is different from each other. Recent studies have shown that the brookite phase is also a suitable photocatalyst due to its orthorhombic structure (less symmetrical) and high bandgap range like anatase. Therefore, using a mixture of anatase-brookite may be increased the recombination rate of pure anatase or rutile. Furthermore, using an anatase-brookite mixture and testing their efficiency over pure anatase or rutile also suitable for chemical and physical stability and homogeneity studies. Hence, changing environmental conditions such as pH and temperature can trigger the conversion of ART (anatase-rutile) or BRT (brookite-rutile) phases. Due to chemical and structural manipulation, traits of TiO<sub>2</sub> such as photocatalytic, biochemical, and antibacterial traits can be quickly shift desired way (Mutuma et al.,

2015). In environmental remediation studies, wastewater treatment by using TiO<sub>2</sub> brookite can provide a beneficial outcome. Many industrial companies and human activities consumed the water. Misusage of water consumption worldwide rapidly increases, and most of the company and scientist wants to discover the technique that can lead people to treat wastewater securely. Wastewater treatment can be possible by the usage of TiO<sub>2</sub>. Exposing TiO<sub>2</sub> onto the wastewater removes the impurities by photocatalytic oxidation and photocatalysis. In the photocatalysis process, excited atoms change their band and create an electron-hole pair. TiO<sub>2</sub> initiates the oxidizing reaction on the compound surface due to its photocatalytic activation, and this process triggers the removal of organic pollutants and impurities by oxidation. Due to solid oxidizing abilities, low cost, and chemical stability, TiO<sub>2</sub> films are used as water filters. The production method is also essential to maintain TiO<sub>2</sub> film's lifetime and cost management. Several methods recognized as a suitable production method for TiO<sub>2</sub>, such as chemical and physical deposition methods, are well-known production methods for TiO<sub>2</sub> films. Moreover, in some conditions, the anatase-brookite mixture tends to provide more photocatalytic activity than single anatase (Freire et al., 2021).

In general, water treatment is done by chlorine and chlorine-based chemicals, but these materials too expensive and include dangerous components for human health such as carcinoma and mutations. Furthermore, due to some limitations of TiO<sub>2</sub>, usage of dopants increase rapidly.

Thus, TiO<sub>2</sub> is doped with several different materials to achieve a higher absorbance rate in recent years, such as Cd, NiO, and graphene-porphyrin. For example, in photocatalytic disinfection of bacteria studies, a porphyrin-doped TiO<sub>2</sub> - was used to examine the biochemical blockage examination of TiO<sub>2</sub>. A porphyrin dopant was designed to increase the absorption rate of TiO<sub>2</sub> in visible light without affecting human life. Pure anatase and the brookite-rutile mixture were prepared for comparison. In addition, the photocatalytic disinfection ability was tested on gram-negative bacteria *Escherichia coli* (*E. coli*) in visible light. In general, gram-negative and gram-positive bacteria are common microorganisms to test, but especially gram-negative bacteria too important for TiO<sub>2</sub> experiments due to their cell wall. The cell wall of gram-negative bacteria contains a thin peptidoglycan layer covered with impermeable double layers containing some lipids and polysaccharides.

Due to its polysaccharide part, the negative charges permit the entrance of positively charged material. This interaction allows the materials to pass inside the cells and cause cell death. Due to this trait, hybrid TiO<sub>2</sub> materials may be used to treat wastewater as a coating material. (Kumar et al., 2021). Phase stability of TiO<sub>2</sub> is so crucial for a variety of applications such as solar systems, thermal protecting systems, aerospace applications, radiation absorption, medical application and solar energy conversion. Due to high demand on this topic, scientists explore new information about which TiO<sub>2</sub> crystalline structure more stable than the others in shockwave pressure circumstances. Recent studies suggest that brookite TiO<sub>2</sub> is more stable under 300 shocks, and anatase TiO<sub>2</sub> tends to transform into a rutile structure under that type of pressure. This information is vital in dealing with high-pressure environments and other critical assessments such as solar energy conversion and radiation absorption. Furthermore, due to its shock-absorbing trait, the brookite phase can be helpful for the harmful environment such as high pressured surfaces, energy conversion applications, biofilm coating (Sivakumar et al., 2021).

In the biodegradation studies, photocatalytic activity differences between pure phases and a mixture of TiO<sub>2</sub> phases are too significant. Fighting against bacteria is a crucial topic for health science, and one of the vital antibiotics in this area is fluoroquinolone (levofloxacin). Fluoroquinolone is used against a variety of harmful microorganisms such as bacteria and pathogens.

However, levofloxacin is not fully degradable in the human body after initial exposure, and the end product is spread into the environment. Due to this problem, levofloxacin degradation is vital for environmental remediation. In addition, adding doping materials on TiO<sub>2</sub> may create side impurities to act as a charge carrier and reduce the overall photocatalysis level of TiO<sub>2</sub> besides other advantages. Due to these problems, some studies suggest using a pure form of TiO<sub>2</sub> and looking at their efficiency against microorganisms.

In theory, a pure TiO<sub>2</sub> not enough to maintain the total photocatalytic activity of degradation. Therefore, a combination of the different TiO<sub>2</sub> phases was used for optimum efficiency. However, the pure brookite TiO<sub>2</sub> effectively fights against the biodegradation of levofloxacin and its wastewater treatment (Lin et al., 2021).

## 2.3 Determination and Discrimination of Experimental Method

In the production of TiO<sub>2</sub>, various methods can be helpful, but the most important thing is time and money consumption. Recently, most of the technological advancement done by the nano-thickness scale and these types of materials provide various abilities in the biomedical, electrical, physical, chemical area. These new properties can be beneficial for bioactivity. The introduction of thin films on bioactivity can be beneficial for various applications. A single or multilayers create these films, and their thickness is changing from nanometers to few micrometers. These thin films contain two parts: the substrate and the layer part. These thin films provide various functions to execute against microorganisms, such as material transformation on wastewater's harmful environment or biodegradation. Due to these unique functionalities, the preparation of thin-film is too crucial for the outcome. Two different deposition techniques are viable in thin-film production, such as physical and chemical depositions (Table 2.3.1).

**Table 2.3.1. Deposition methods**

| <b>Chemical Deposition Techniques</b>     | <b>Physical Deposition Techniques</b>      |
|---|--|
| <b>1. Chemical Vapor Deposition (CVD)</b> | <b>1. Sputtering techniques</b>            |
| Low pressure (LPCVD)                      | Direct current sputtering (DC sputtering)  |
| Plasma enhanced (PECVD)                   | Radio frequency sputtering (RF sputtering) |
| Atomic layer deposition (ALD)             | <b>2. Evaporation Techniques</b>           |
| <b>2. Plating</b>                         | Vacuum thermal                             |
| Electroplating technique                  | Electron beam                              |
| Electroless deposition                    | Arc evaporation                            |
| <b>3. Chemical bath deposition</b>        | Molecule Beam epitaxy                      |
| <b>4. Sol-gel technique</b>               | Ion Plating                                |
| <b>5. Spray pyrolysis technique</b>       | Laser Beam                                 |
| <b>6. Hydrothermal synthesis</b>          | <b>3. Ball milling</b>                     |
| <b>7. Spray coating</b>                   |  |

All these deposition methods have unique ways to produce TiO<sub>2</sub> thin films, but determination and discrimination of most valuable methods are done according to cost, time-consuming, stability, and homogeneity. In between these two main deposition methods, our experiment more suitable for the chemical deposition method. Therefore, all standard deposition methods are listed and due to our limitation of budget and time interval analysis, choosing the sol-gel method is more beneficial for the experimental process (Table 2.3.2).

**Table 2.3.2. Chemical deposition methods for TiO<sub>2</sub> thin film and their advantages as well as limitations**

| Method                          | Description  | Advantages   | Limitations   | Ref.  |
|---------------------------------|--|--|---|---|
| Chemical Vapor Deposition (CVD) | A chemical reaction between the substrate and volatile precursors  | <ul style="list-style-type: none"> <li>-Easy method</li> <li>-Less contamination</li> <li>-Flexible</li> <li>-High density</li> </ul>  | <ul style="list-style-type: none"> <li>- Toxic and flammable</li> <li>-Needs higher reaction temperature</li> <li>- Low deposition rate</li> <li>-More than one material creates chaos</li> </ul> | (Yemmireddy & Hung, 2017) (Patil, Shaikh, & Ibram, 2015)                |

## 2.4 Sol-Gel Method

The sol-gel method is a beneficial deposition technique to obtain a thin film for several different usage areas such as biomedical, chemical and electrical (Varshney et al., 2016). The sol-gel method was chosen for this experiment because of its unique traits such as homogeneity, sustainability, effectiveness, and low cost (Pant, Park, & Park, 2019). Homogeneity is crucial for this experiment because this experiment mainly focused comparison of ZnO doped TiO<sub>2</sub> thin films with pure TiO<sub>2</sub> thin films. Furthermore, the most significant advantages of using the sol-gel method are; it is carried out at room temperature and enhance various functions at a low cost (Pant, Park, & Park, 2019).

In general, the sol-gel method is a method of gel production derived from precursor metal alkoxides by using hydrolysis and condensation reactions (Jilani, Abdel-wahab, & Hammad, 2017). The primary sol-gel method has four steps: sol production, hydrolysis, condensation, drying (gel formation) (Aguilar, 2018) (Figure 2.4.1).

The starting materials generally chose from inorganic metal salt or metal alkoxides (Jilani et al., 2017). The sol-gel method offers the transition of solution (sol) into a solid (gel) phase. The “Sol” phase initially started with the dispersion of metal alkoxides or inorganic salt. After producing the “sol” phase, a solvent in the solution begins to evaporate, the left particles or ions begin to join and create a continuous network.

This continuous network creates a web structure, and this newly formed structure is called “gel.” (Figure 2.4.1). However, acid and base addition can form a more dense or strict network (Aguilar, 2018). Transition to van der Waals bond interaction to covalent bond makes this process irreversible (C. Brinker, 1990). The main advantage of the sol-gel method is dissolving the precursor material in liquid with controlled stoichiometry. The rate of reaction can be easily controlled by temperature. This controlled stoichiometry prevents contamination and provides a suitable environment for mixing multi-compounds in the same solution. Shape, viscosity, porosity and texture can be controlled by changing dynamics of the sol-gel method (Dulian et al., 2019).

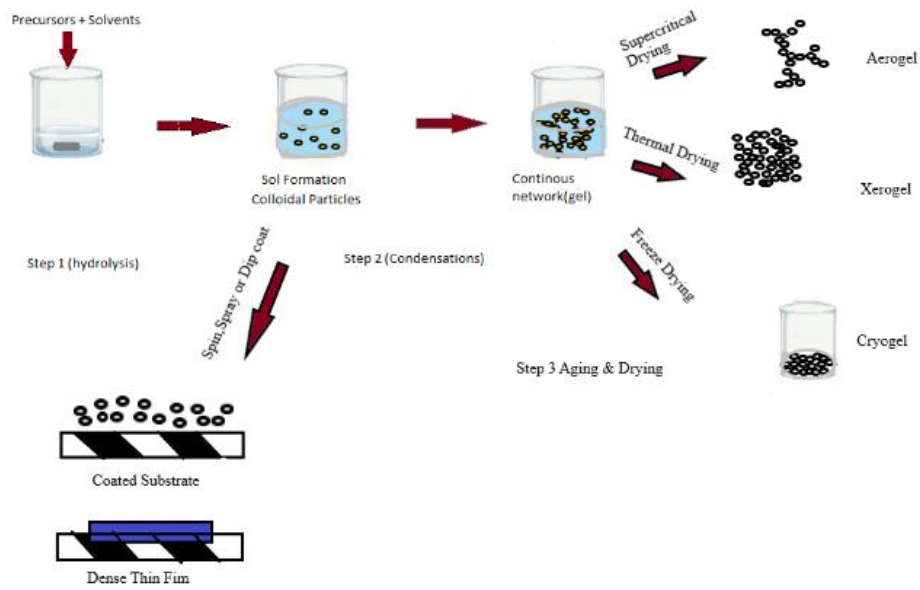

Figure 2.4.1. Stages of the sol-gel technique

Figure 2.4.2. Reactions of sol-gel method

## 2.5 Doping Material

Doping is a commonly used method that provides various electrons and holes in semiconductors. In general, doping is known to modify conductivity by adding new materials into a semiconductor crystal. For example, doping of  $\text{TiO}_2$  with various dopants forms new energy levels, and that process increases  $\text{TiO}_2$  photocatalytic activity. However, doping material divides into two types: N and P-type doping. N-type doping is created between the material with a 4-valence electron semiconductor and a 5-valence electron dopant material—P-type material created between the material with 4-valence electron semiconductor and 3-valence electron dope material ((Khlyustova et al., 2020). N-type dopant increases the number of available electrons because dopant has one more valence electron than semiconductor (Table 2.5.1).

On the other hand, P-type dopant increases the number of holes because dopant has only three valence electrons that are less than semiconductor, and both these processes increase the conductivity of the semiconductor by changing bandgap energy differently. In general, the bandgap represents the minimum energy level for one electron, the jump next energy level where it can join in conduction (Khlyustova et al., 2020). Thus, a bandgap is a distance between the valence band and the conduction band (Figure 2.5).

**Figure 2.5. Representation of N-type and P-type of semiconductor**

**Table 2.5.1. Doping Material features**

|          | N-type            | P-type            |
|----------|-------------------|-------------------|
| Bonds    | Extra Electron    | Less Electron     |
| Dopant   | 5-valent electron | 3-valent electron |
| Carriers | Electrons         | Hole              |

Many researchers have been studied various dopants for TiO<sub>2</sub> thin film experiments. Those dopants enhance the thin film photocatalytic and antibacterial activity in various ways (Norton et al., 2004). ZnO was chosen for this experiment because it has good electron mobility at room temperature and has an expansive bandgap energy of 3.37 eV compared to TiO<sub>2</sub> phases (Firdaus, Rizam, Rusop, & Hidayah, 2012). TiO<sub>2</sub> and ZnO are known as excellent semiconductors. However, their characteristics are different such as TiO<sub>2</sub> is an indirect semiconductor meanwhile ZnO is a direct semiconductor.

However, TiO<sub>2</sub> thin films present two limitations during photocatalytic activities: low use of solar spectrum and high recombination rate (Firdaus et al., 2012). ZnO is a good candidate for compensating for these limitations due to its unique traits. Recently, many researchers took advantage of nanocomposite materials due to their enhancing traits on optical, electrical and structural properties (Table 2.5.3) (Firdaus et al., 2012). Furthermore, dopants can increase the electron transfer efficiency of semiconductors. Hence, using noble metal ions, such as Au, Ag, Pt and Pd as a dopant can enhance the photocatalytic efficiency in various ways; catching electrons and reduce the recombination rate, and empower the light absorption in the visible range (Bensouici et al., 2015).

Overall, the addition of dopants can manipulate photocatalytic, chemical, and antimicrobial activity. However, combining new materials as a dopant still needs to improve because every different concentration of dopants can provide new outcomes.

**Table 2.5.2. Specific features and values of ZnO material**

| Features       | Value                    |
|----------------|--------------------------|
| Density        | 5.6006 g/cm <sup>3</sup> |
| Melting Point  | 1975 °C                  |
| Energy gap     | 3.36 eV                  |
| Binding energy | 60 meV                   |

## 2.6 UV-vis Spectroscopic Method

Ultraviolet-visible (UV-vis) spectrophotometer is an absorbance determination material used to understand materials' optical features in solution or solid phase. This device tracks the excited atoms by looking at their wavelength and absorbance energies. UV-vis spectrophotometer detects the absorbance of the film between the range of 200-1100 nm spectrum (Skoog, West, Holler, & Crouch, 2004). The absorbance value is calculated by Beer-Lambert law (Equation 2.6.1).

For the single wavelength,  $A$  is absorbance (unitless),  $\epsilon$  is known as an molar absorptivity (molar,  $M^{-1}cm^{-1}$ ),  $b$  is the length of the path (cm),  $c$  is solution concentration (M),  $I_0$  is the intensity of light at a specific wavelength, and  $I$  is the transmitted intensity (Skoog et al., 2004). Moreover, UV-vis spectroscopy can provide quantitative and qualitative information about of sample (Skoog et al., 2004).

$$A = \log_{10}(I_0/I) = \epsilon bc, \quad (2.6.1)$$

**Figure 2.6.1.** (a) Representation of resonant and non-resonant band (b) Representation of Height and Width at half height (FWHM)

In UV-vis spectrophotometric analysis' most crucial part is finding the area under the curve because the area under the curves gives the resonance ratio. The resonance ratio is an essential concept for homogeneity, and it has been calculated by dividing the resonant band area into a non-resonant band area. In addition, another critical concept called normalized width is calculated by the division of width of the resonant band into the height of the resonant band-both resonance ratio and normalized width important for optical analysis of materials (Tan & Resasco, 2005).

$$\text{Resonance ratio} = \text{Area of resonant band} / \text{area of the nonresonant band} \quad (2.6.2)$$

$$\text{Normalized width} = \text{Width of resonance band} / \text{height of the resonant band} \quad (2.6.3)$$

## 2.7 XRD Analysis

XRD is a widely used analytic method for physical and chemical composition identification. XRD instruments include three elements: a sample holder, an X-ray detector, and an X-ray tube. Generally, cathode tubes create the X-ray and voltage applied for accelerating the electrons than electrons bombarding the target material. Therefore, the XRD helpful method for analyzing homogeneity, crystal property, and average particle size. In general, XRD creates monochromatic X-rays, and these X-rays are scattered at specific angles to create specific peaks according to a sample's crystalline structure (Brady & Boardman, 1995).

Every material has a unique set of d-spacing which means converting diffraction peaks to d-spacing reveals the type of the material. Due to these traits, the XRD pattern reveals the atomic composition of the material. Moreover, XRD analysis provides the atomic position of the crystalline structure. XRD analysis application on thin films provides information about lattice formation between substrate and film, homogeneity of materials, quality of the film, thickness, and toughness of the thin film (Jeans, 1998). The XRD result shows the average crystal size using Scherrer's equation (Equation 2.7). In Equation 2.7,  $D$  represents the diameter of the  $\text{TiO}_2$  nanocrystals,  $K$  presents the shape factor, and it has a constant value (0.89),  $\lambda$  represents the radiation wavelength,  $B$  represents the full width at half maximum (FWHM) of the diffraction line, and  $\theta$  (theta) represents the Bragg angle (rad) (Valerio & Morelhão, 2019).

$$D = \frac{K \lambda}{B \cos \theta}, \quad (2.7)$$

## 2.8 Antibacterial Measurement

The antibacterial activity of  $\text{TiO}_2$  is crucial for biodegradation, wastewater remediation and antibacterial disinfection.  $\text{TiO}_2$  thin films used various applications related to antibacterial activity, and most of them are mentioned (Section 2.2). The advantages of  $\text{TiO}_2$  are photocatalytic activity, high degradation efficiency and non-toxicity (Phuinthiang et al., 2021). Due to these traits,  $\text{TiO}_2$  thin film can provide a suitable solution for antibacterial disinfection studies.

Antibacterial materials rapidly grow in recent years, and most technological advancements need to provide antibacterial traits. Therefore, the ISO 22196 method was used to determine the antibacterial activity of TiO<sub>2</sub> thin films. In addition, ISO 22196 is a method that quantitatively evaluates the antibacterial activity (growth inhibition or killing) of samples such as plastic, other non-porous, and surface products (ICS, 2011). Therefore, ISO 22196 is an excellent method to determined bacteriostatic (growth inhibition) and bactericidal (killing bacteria) features and this test highly critical for TiO<sub>2</sub> usages for future technologies.

Different types of pure and doped TiO<sub>2</sub> thin film antibacterial efficiencies were represented (Table 2.8).

**Table 2.8. Antibacterial efficiency of different types of Pure TiO<sub>2</sub> and doped TiO<sub>2</sub>**

### **3. METHODS AND MATERIALS**

#### **3.1 Experimental Process**

##### **3.1.1 Production of Brookite Phase**

The nanostructured TiO<sub>2</sub> sol was prepared using a mixture of titanium tetra isopropoxide (Ti [OCH(CH<sub>3</sub>)<sub>2</sub>]<sub>4</sub>; (TTIP) Sigma-Aldrich), H<sub>2</sub>O, nitric acid (HNO<sub>3</sub>), deionized water (DI), and isopropanol. First, titanium tetra isopropoxide (TTIP) was dissolved in isopropanol. Nitric acid was added dropwise in the solution under continuous stirring. Deionized water was added for hydrolysis. As a solution of TTIP:isopropanol:DI:AcAc a volume ratio of (0.4:4:0.1:0.2) was used. The solution was mixed using magnetic stirring for three hours at a room temperature of 22 °C.

##### **3.1.2 Production of Anatase Phase**

Titanium tetra isopropoxide (Ti [OCH(CH<sub>3</sub>)<sub>2</sub>]<sub>4</sub>; (TTIP) Sigma-Aldrich) was mixed with acetic acid and ethanol with a molar ratio of 0.08:0.48:4, respectively. The mixture was stirred for two hours at a room temperature of 22 °C.

##### **3.1.3 Production of Rutile Phase**

Tetrabutyl orthotitanate (Ti (OCH<sub>2</sub>CH<sub>2</sub>CH<sub>2</sub>CH<sub>3</sub>)<sub>4</sub>; TBOT) was dissolved in ethanol under vigorous stirring for 30 minutes. Then, in another beaker, ethanol was mixed with Hydrochloric acid (HCl) for 30 minutes. Afterward, the second solution in the other beaker was slowly added dropwise to the first solution under vigorous stirring until homogeneous. Then, preparation of the TiO<sub>2</sub> films with various crystal phases, the solutions prepared by the sol-gel process was spin-coated on the corning 2947 substrates. Next, the films were heat-treated at 450 °C for one hour, for brookite and anatase crystal phases, at 600 °C for the rutile crystal phase. After the heat treatment, one layer was formed on the surface of the films. Then, the films were coated with a spin coater again, paying attention to the TiO<sub>2</sub> solution coated side on the upper surface, and heat treatment and spin coating processes were continued until the films are 3-layered.

### 3.1.4 Production of ZnO (wurtzite)

The solution was prepared by dissolving zinc acetate dehydrate (ZnAc) in isopropanol. Dea (Diethanolamine), which is a surface-active material, is used to accelerate solving. Water was added for hydrolysis reactions, as a precursor solution of ZnAc:isopropanol:Dea: water, a volume ratio of 0.4:4:0.1:0.2 was used. The solution was mixed using magnetic stirring for one hour at 60°C.

### 3.1.5 Production of ZnO/TiO<sub>2</sub> material

The obtained solution in Section 3.1.4 was mixed with one of the leading TiO<sub>2</sub> solutions for brookite, rutile, or anatase phase at ZnO/TiO<sub>2</sub> volume ratios of 0, 0.01, 0.02, 0.05, 0.1, denoted as ZTA0-10, ZTB0-ZTB10, ZTR0-ZTR10, respectively. The final solutions were deposited on corning 2947 glass substrates by spin-coating deposition (1000 rpm/30 s), using a spin coater at room temperature (22°C). After coating, ZnO films were immediately placed in a microprocessor-controlled (CWF 1100) furnace, heated at 450°C. The films were taken out of the furnace and left at room temperature at the end of 1 hour. Finally, the all coatings and heat treatment processes were repeated two times in order to get 3-layered films.

### 3.1.6 Antibacterial measurements of thin films

Surfaces were needs to be smooth, 1cm thick, and 5x5 cm<sup>2</sup> shapes. Six samples of a corning glass covered with thin films were prepared for the experiment; three samples to test bacteria and three to control groups. Each of these samples (TiO<sub>2</sub>, ZnO/TiO<sub>2</sub>) was analyzed by ISO 22196.

In antibacterial analysis, gram-positive “*Staphylococcus aureus*” and gram-negative “*Escherichia coli*” were used. The antibacterial activity of the films was evaluated by colony forming unit (CFU) counting. After incubation, the colonies were counted. CFU per ml was calculated for each sample at different time intervals (0-120 min) by using the following formula:

$$\text{CFU/ml} = \text{No. of colonies} \times \text{Dilution factor} / \text{volume inoculated}$$

### 3.2 Characterizations

The absorbance spectra of composite films were measured using Labomed Spectro 22 UV–vis Spectrophotometer in the spectral range of 190–1100 nm wavelengths. The calculations of under the curve area, the entire width of half maximum of the absorbance data were performed by Origin 8.0 Software focusing the absorbance peak regions. The optical band gap energies of the composite films were calculated from the Tauc Plot since the thickness of the films was suitable for applying Beer-Lambert’s Law. For identifying the films' crystal phases, an X-ray diffractometer (XRD, Philips PW-1800) with Cu-K $\alpha$  radiation (The wavelength of Cu-K $\alpha$  is 0.15406 nm) was used. The antibacterial response of the films was investigated using gram-positive “*Staphylococcus aureus*” (*S. aureus*) and gram-negative “*Escherichia coli*” (*E. coli*) according to the standard of ISO 22196. The initial dose of these bacteria’s concentration was 10<sup>5</sup>CFU/ml. Since TiO<sub>2</sub> shows antibacterial properties under UV light exposure and its photocatalytic effect is known, the antibacterial effect in the visible light region was investigated by doping with ZnO.

## 4. RESULTS AND DISCUSSION

### 4.1 XRD Results

The particle diameter size of different thin films was calculated according to Equation 2.7. The most crucial thing in the calculation is the theta value. Generally, theta value is found with two thetas and must need to convert single theta value to determine the diameter of particles properly. Then, the calculation and comparison of the XRD values were determined (Table 4.1 1).

**Table 4.1.1. XRD values of different types of thin films and their diameter size**

| Thin films                  | Parameters |                     | Calculations             |      |       |

In this study, decreased size diameter needs to be achieved after using ZnO as a dopant material. The average particle size of ZnO was found at 51.51 nanometers. The average size of pure TiO<sub>2</sub> phases anatase at 21.86 nm, brookite was at 50.18 nm, and rutile was at 36.9 nm. ZnO doped anatase TiO<sub>2</sub> (ZTA) XRD data shows that a small concentration of ZnO doped increases the diameter size of TiO<sub>2</sub> then decreases the composite size slowly after adding more ZnO concentration. In ZnO doped brookite TiO<sub>2</sub>(ZTB), XRD data shows that adding every amount of ZnO into brookite decreases the diameter size due to brookite orthomorph structure. ZnO doped rutile TiO<sub>2</sub> XRD data shows that the addition of ZnO also decreases the average particle size of pure slowly. This slow increase and decrease of particle size in ZTR(doped rutile) and ZTA(doped anatase) related to their tetragonal structure. Symmetrical structure affects the bond formation and hindering.

Figure 4.1.2. (a) shows that the films have a rare brookite phase, an orthorhombic crystal structure. A single crystallization peak (211) of the brookite phase at a 2 $\theta$  value of 31.5° corresponds to ICDD Card No. 04-019-9878. In Figure 4.1.1.(c), the sharp diffraction peaks at 25.2°, 37.7°, and 47.8° theta values are indexed to the (101), (004), and (200). Planes of the anatase phase of TiO<sub>2</sub> correspond to 21-1272 according to ICDD Card. In Figure 4.1.1. (d), the peaks at the 2 $\theta$  values of 27.31°, 36.12°, and 41.25° are fitted well with the (110), (101), and (111) planes of the rutile phase of TiO<sub>2</sub> (ICDD Card No. 21-1276), respectively. These (anatase and rutile) are tetragonal phases of TiO<sub>2</sub>.

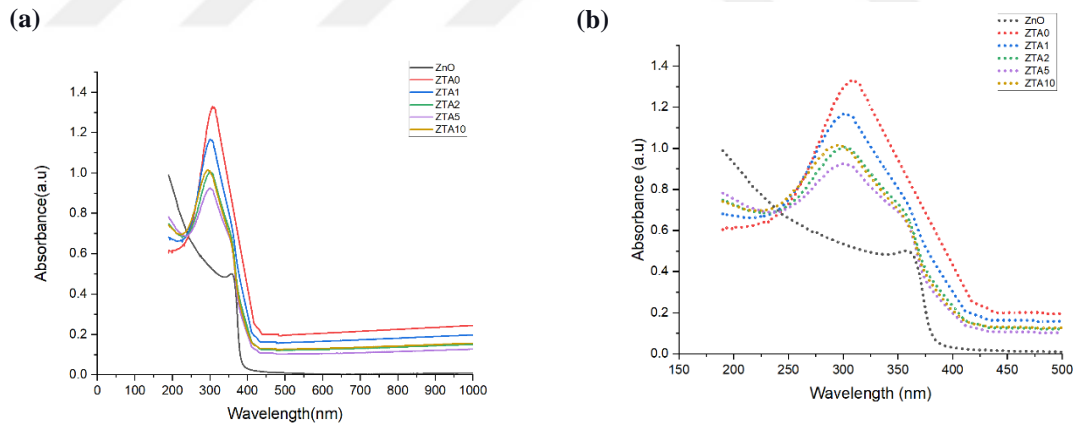

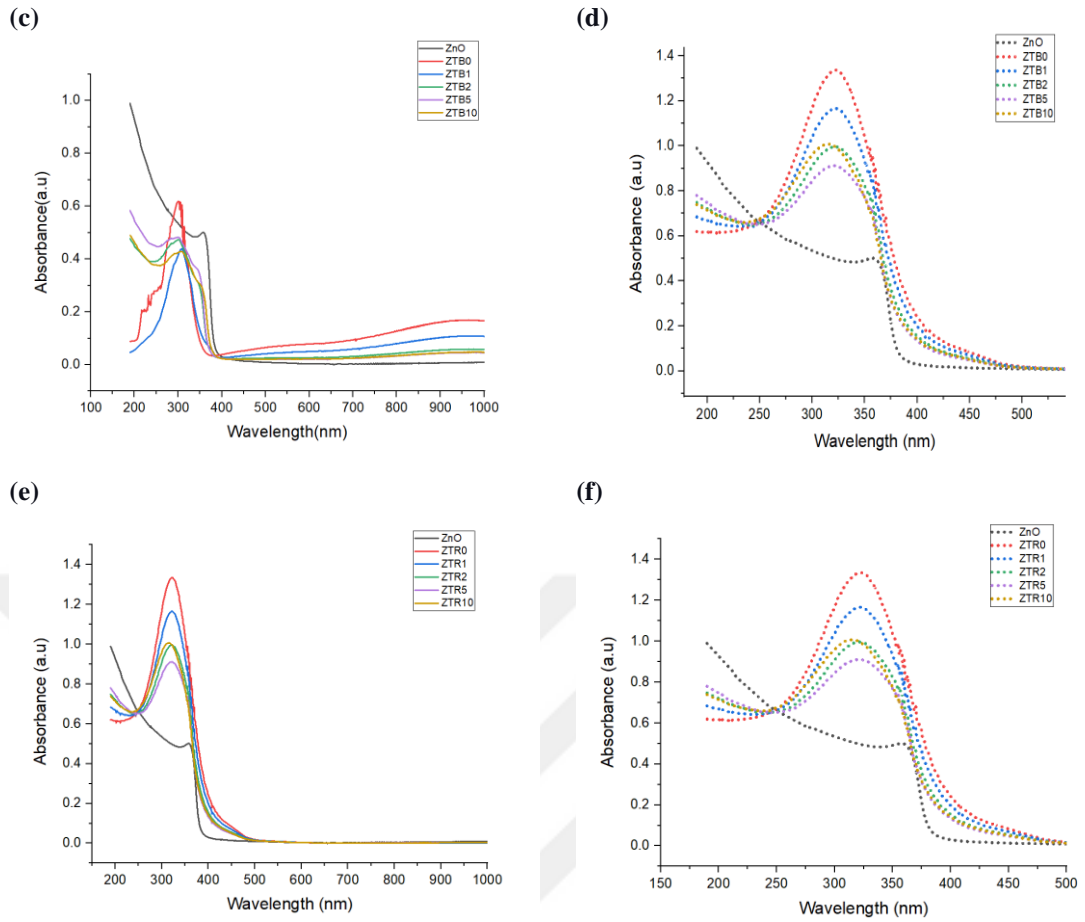

**Figure 4.1.3.** XRD response of (a) ZnO doped TiO<sub>2</sub> brookite films with various ZnO/TiO<sub>2</sub> doping ratios, (b) ZnO film and parameter calculations, (c) ZnO doped TiO<sub>2</sub> anatase films with various ZnO/TiO<sub>2</sub> doping ratios, (d) ZnO doped TiO<sub>2</sub> rutile films with various ZnO/TiO<sub>2</sub> doping ratios.

## 4.2 Optical Results

Absorption spectra of pure TiO<sub>2</sub> films and ZnO doped TiO<sub>2</sub> films were analyzed using UV-vis spectrophotometers, as shown in Figure 4.2.1. High absorbance values are seen between at 200-500 range. According to absorbance-wavelength graphs, the addition of ZnO can enhance the absorbance rate of all three phases. The high absorbance value of ZnO can decrease the absorbance range of Pure TiO<sub>2</sub> phases because of dilution of pure TiO<sub>2</sub> absorbance ability reduce, and the addition of ZnO introduces its photon absorbance rate. Recombination of rate increases, and absorption of doped nanocomposites decreases. The addition of ZnO also affects the resonance ratio and homogeneity of the material. Doped material may enhance the photocatalytic activity, but the optimum

amount of dopant addition so important for homogeneity concerns. A comparison of different volumes of ZnO doped anatase, brookite, and rutile was determined (Figure 4.2.1 to 4.2.4). In normal conditions, the homogeneity of material is determined by the relation between resonance ratio and normalized width. When the resonance ratio increase and normalize width decreases, that implies composites reach a more homogenous structure. According to calculations, the addition of ZnO dopant decreases the resonance ratio and increases the normalized width, which is vice versa of literature information. However, our studies do not ultimately increase or decrease; it has some ranges in which composites resonance ratio increases with ZnO. This result provides a piece of good information such as critical point to cut down dopant addition to getting the more homogenous structure. Further studies can arrange their dopant addition to these ranges to get more homogenous material. ZTA5-10, ZTB5-10, and ZTR5-10 concentration ranges are critical for the homogeneity shift for excessive dopant addition (Table 4.2.1).

### 4.3 Bandgap Energy

In band energy analysis, the Tauc plot was used to measure materials' band-gap energies (Equation 4.3.1). In general, Titanium dioxide ( $\text{TiO}_2$ ) is an excellent semiconductor in terms of bandgap energy, such as anatase 3.20 eV, rutile 3.00 eV, and brookite 3.13 eV (Linsebigler, Lu, & Yates, 1995; Thiyagarajan, Sivakumar, & Rajangam, 2016; Wang, He, Lai, & Fan, 2014). In this part, the photocatalytic ability of pure  $\text{TiO}_2$  and ZnO doped  $\text{TiO}_2$  was determined. In a normal condition, ZnO addition needs to increase the bandgap energy of pure  $\text{TiO}_2$ , but  $\text{TiO}_2$  is an indirect semiconductor, and ZnO is a direct conductor. Thus every possible indirect and direct graphs need to be evaluated for optimum results (Figure 4.3.1). These graphs find from the absorbance value of every single material. In direct conduction, the r variable equal to 2 and the indirect conduction r variable equal to  $\frac{1}{2}$ . After creating their Tauc plots, ZnO doped anatase tend to direct conductor, ZnO doped brookite tend to the indirect conductor, and ZnO doped rutile tend to act like a direct conductor. Discrimination of indirect and direct conduction is done by using the Tauc plot. ZnO normal bandgap energy around at 3.37 eV (Firdaus, Rizam, Rusop, & Hidayah, 2012). The addition of ZnO dopant needs to increase the original bandgap energy of pure  $\text{TiO}_2$  phases. Due to this reason, (a),(d),(e) in Figure 4.3.1 shows that the addition of ZnO dopant increases the original band gap energy of  $\text{TiO}_2$ .

$$(\alpha h\nu) = B(h\nu - E_g)^r \quad (4.3.1)$$

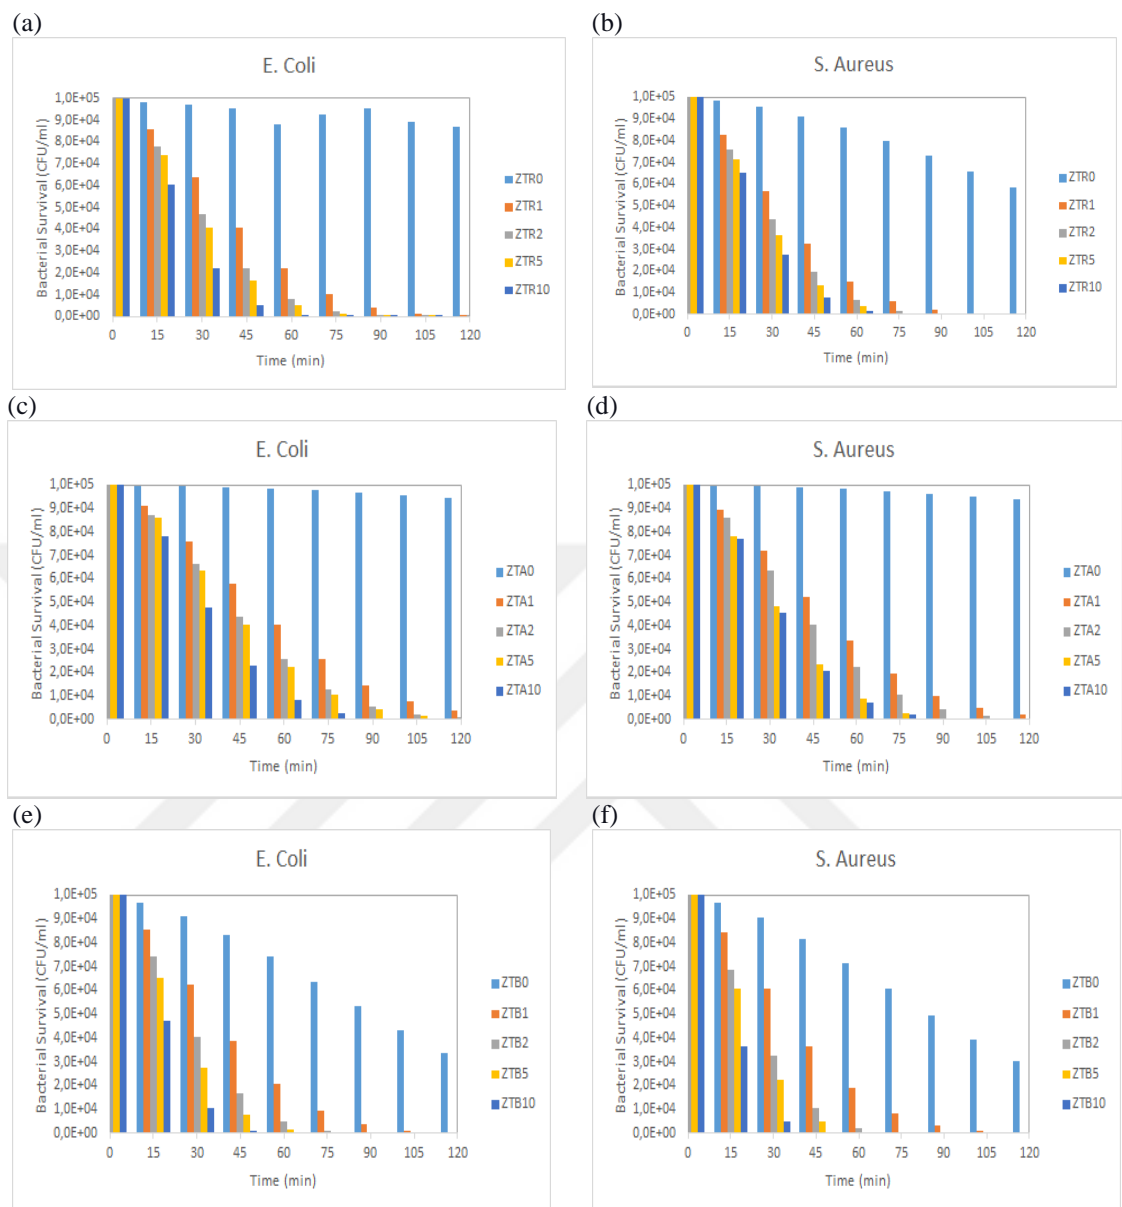

**Figure 4.3.2.** Tauc Plot of pure ZnO and ZnO doped Anatase, Brookite, and Rutile phases of TiO<sub>2</sub> with various ZnO/TiO<sub>2</sub> ratios. The extrapolation of the curves shows the optical energy band gap of ZTA, ZTR, and ZTB.

**Table 4.3.1.** Bandgap energy values of different types of doped material derived from the Tauc plot.

#### **4.4 Antibacterial Activity**

Figure 4.4.1 presents the antibacterial response of films with respect to the time for *E. coli* and *S.aureus*. *E. coli* count reduced from  $10^5$  to  $10^4$  with 120 min of irradiation time for pure brookite  $TiO_2$  film. A dramatic decrease of the bacteria number for both bacteria was observed for ZnO/ $TiO_2$  composite films compared with that of  $TiO_2$  films under the lighting with visible light. After 120 min. of light exposure, the bactericidal survival decrease of ZTA0, ZTA1, ZTA2, ZTA5, and ZTA10 films against *E. coli* were  $10^0$ ,  $3 \times 10^1$ ,  $10^2$ ,  $2 \times 10^2$  and  $7 \times 10^3$ , respectively. Meanwhile, exhibiting a similar trend, the bactericidal survival decrease of ZTA0, ZTA1, ZTA2, ZTA5, and ZTA10 films against *S. aureus* were  $10^0$ ,  $5 \times 10^1$ ,  $2 \times 10^2$ ,  $6 \times 10^3$  and  $10^4$ , respectively. For ZTB2-ZTB10 films, complete inactivation of the *E. coli* was recorded at 120, 90, and 75 min of light exposure, respectively. Since  $TiO_2$  shows antibacterial properties under UV light exposure and its photocatalytic effect is known, the antibacterial effect in the visible light region was investigated by doping with ZnO. These results show that the content of ZnO in the ZnO/ $TiO_2$  composite films plays a significant role for enhancing the antibacterial activity of the films in the absence of UV light.

**Figure 4.4.3.** Antibacterial response of ZnO doped Anatase, Brookite, and Rutile phases of TiO<sub>2</sub> with various ZnO/TiO<sub>2</sub> ratios under light exposure for *E. Coli* and *S. Aureus*.

## 5. CONCLUSION

In conclusion, XRD results show that the particle size of  $\text{TiO}_2$  can be reduced in the brookite phase rather than anatase and rutile due to brookite's large volume. However, anatase and rutile also show remarkable diameter size drop when the concentration is appropriately arranged. Due to their stability traits, anatase and rutile particle size decrease slowly. UV data show that the resonance ratio is essential for cell homogeneity and dispersibility. Due to this reason addition of dopant materials needs to be controlled by stoichiometry for optimum homogeneity. Using the sol-gel method provides the minor homogeneity range for ZnO doped  $\text{TiO}_2$  in a concentration of doped ZTA5-10, ZTB5-10, and ZTR5-10. After all these properties, band gap energy enhancement of ZnO was showed by using Tauc plot. Direct ZnO doped anatase  $\text{TiO}_2$ , direct ZnO doped rutile and indirect ZnO doped brookite conduction bands showed. According to antibacterial activity test results, the ZnO doping of composite films boost the inactivation of bacteria under visible light. This thesis mainly focused on discovering how dopant material can enhance the activity of pure material and how these enhanced traits can be used on optical and antibacterial activity. Therefore, ZnO/ $\text{TiO}_2$  composite films can give an alternative solution for antibacterial surface applications under visible light.
